

¹ Exploring the Composition of Lithic Assemblages in Mesolithic
² South-Eastern Norway

⁴ 04 August, 2021

⁵ **Abstract**

This paper leverages multivariate statistics to explore the composition of 54 Mesolithic assemblages located in south-eastern Norway. To provide analytical control pertaining to factors such as variable excavation practices, systems for artefact categorisation and raw-material availability, the sites chosen for analysis have all been excavated relatively recently and have a constrained geographical distribution. The assemblages were explored following two strains of analysis. The first of these entailed the use of artefact categories that are established within Norwegian Mesolithic archaeology, while the other involved drawing on measures that have been linked directly to land-use and mobility patterns associated with lithic assemblages more widely. The findings pertaining to the established artefact categories largely reflect the temporal development previously reported in Norwegian Mesolithic research, which has been based on more subjectively driven methods. Furthermore, the chronological trends associated with variables taken from the so-called Whole Assemblage Behavioural Indicators (e.g. Clark and Barton 2017), originally devised for characterising Palaeolithic assemblages in terms of associated mobility patterns, also align with the development previously proposed in the literature. This provides an initial indication that these measures are applicable in a Norwegian Mesolithic setting as well, setting the stage for a more targeted and rigorous model evaluation outside this exploratory setting. Furthermore, this finding supports the notion that these measures can offer a powerful comparative tool in the analysis of lithic assemblages more generally.

²³ **Highlights**

- Multivariate exploratory analysis of Mesolithic assemblages in south-eastern Norway
- Explores relevance of artefact categories established in Norwegian archaeology
- Explores variables associated with mobility patterns in lithic assemblage studies
- Draws on the Whole Assemblage Behavioural Indicators (WABI)
- Relevance for Mesolithic Norway supports the notion that WABI are widely applicable

²⁹ Keywords: Mesolithic Scandinavia; Multivariate statistics; Mobility strategies; Whole Assemblage Behavioural

³¹ **1 Introduction**

This study employs multivariate exploratory statistics to analyse lithic assemblages associated with Mesolithic sites located in south-eastern Norway. This is done to identify latent patterns and structure in the relationship between the assemblages, with the ultimate aim of identifying behaviourally induced variation in their composition across time. However, the composition of the assemblages can be expected to be determined by a multitude of factors (e.g. Dibble et al. 2017; Rezek et al. 2020), ranging from the impact of natural formation processes, to various and intermixed behavioural aspects such as purpose, duration, frequency and group sizes at visits to the sites. The assemblages are also likely to be impacted by variation in lithic technology, artefact function, use-life and discard patterns, as well as procurement strategies and access to raw materials. Finally, analytic and methodological dimensions relating to survey, excavation and classification practices are also fundamental to how the assemblages are defined. Consequently, the analysis conducted here is done from an exploratory perspective, where all of these factors should be seen as potential contributors to any

43 observed pattern. In an attempt to limit the influence of some potentially confounding effects, the material
44 chosen for analysis has a constrained geographical distribution, and stems from recent investigations that
45 have employed comparable methods for excavation and classification within larger unified projects.

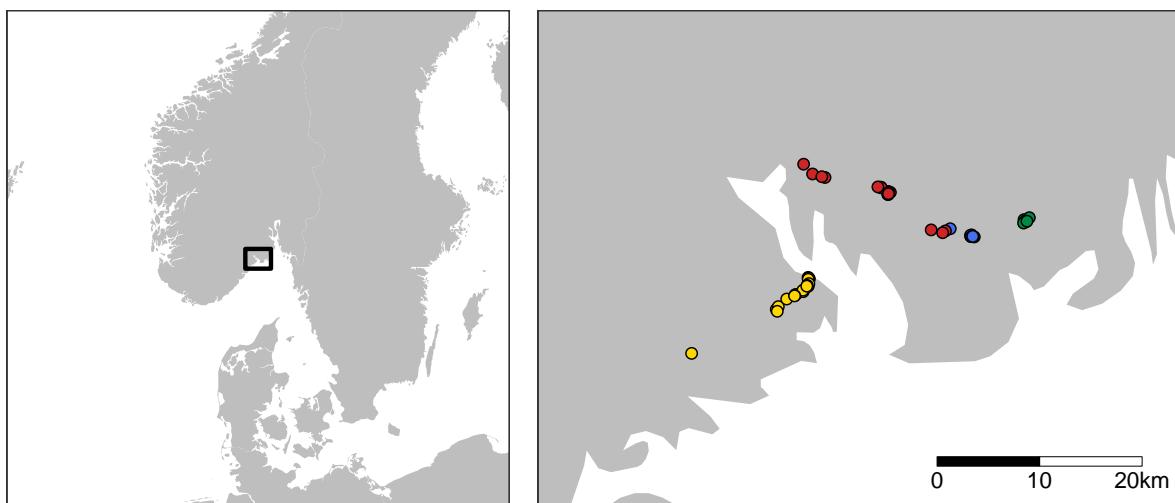

46 Even though each individual assemblage can have been impacted by an virtual infinitude of effects that might
47 skew an archaeological interpretation, this does not preclude the applicability of inductive analyses aimed
48 at revealing overarching structure in the data without imposing overly complex analytical frameworks that
49 attempt to account for these particularities (Bevan 2015). Structure that can be revealed from considering all
50 of the assemblages in aggregate can constitute a step in an iterative analytical chain that ultimately aims to
51 tease apart the multitude of factors that have shaped the composition of the assemblages, and should be of
52 value to subsequent in-depth studies of any individual site. The most immediate danger of the approach
53 outlined here is rather to be overly naive in the causal significance and cultural importance that is ascribed to
54 any identified pattern. As such, the main aim of this analysis is to compare the results with findings reported
55 in previous literature concerned with the Mesolithic in southern Norway and have the generation of new
56 hypotheses as a possible outcome. To this end, the analysis follows two analytical avenues. The first involves
57 an analysis of the assemblages using the classification of the artefacts done for the original excavation reports.
58 The second involves an analysis of the assemblages in light of the so-called Whole Assemblage Behavioural
59 Indicators (e.g. Clark and Barton 2017), which have been employed in other contexts to align properties of
60 lithic assemblages with land-use and mobility patterns.

61 2 Archaeological context and material

62 The Early Mesolithic, or Flake Axe Phase, is defined as lasting from c. 9400–8200 BCE (Table 2), and is set
63 to start with the first recorded human presence in Norway (Damlien and Solheim 2018). Previous research
64 has typically proposed that the Early Mesolithic is characterised by a relatively high degree of mobility,
65 and low variation in site types and associated mobility patterns (e.g. Bjerck 2008; Breivik and Callanan
66 2016; Fuglestvedt 2012; but see Viken 2018). Around the transition to the subsequent Middle Mesolithic
67 or Microlith Phase at c. 8200 BCE, pervasive changes in blade and axe technology occur (Damlien 2016;
68 Eymundsson et al. 2018; Solheim et al. 2020), which in turn has been associated with changes in population
69 genomics and related migration events hailing from the Eurasian steppes (Günther et al. 2018; Manninen et
70 al. 2021). The Microlith Phase is defined as lasting until around 7000 BCE, which is followed by the Pecked
71 Adze Phase, characterised by a more dominating presence of non-flint macro tools and associated production
72 waste in the assemblages (Reitan 2016). The next typological transition at c. 5600 BCE signifies the onset of
73 the Nøstvet Adze Phase. While previously defined as having a slightly longer duration, the Nøstvet Phase
74 has traditionally been seen as representing the onset of more varied settlement systems and stable mobility
75 patterns (e.g. Jakslund 2001; Lindblom 1984). In recent years it has been suggested that the transition to a
76 decrease in mobility and more varied land-use patterns can be traced back to the Middle Mesolithic (Solheim
77 and Persson 2016). The subsequent Transverse Arrowhead Phase (c. 4500–3900 BCE) is characterised by a
78 dramatic decrease in axe finds, and the introduction of new flint projectiles (Reitan 2016). It has recently
79 been suggested that a dispersal of people from southern Scandinavia into southern Norway takes place in this
80 period (Eigeland 2015:379; Nielsen 2021), which could follow after a preceding population decline at c. 4300
81 BCE Solheim and Persson (2018).

82 A defining characteristic of the Norwegian Mesolithic is that a clear majority of the known sites are located
83 in coastal areas (e.g. Bjerck 2008). Furthermore, these coastal sites appear to predominantly have been
84 located on or close to the contemporary shoreline when they were in use (Åstveit 2018; Breivik et al. 2018;
85 Møller 1987; Solheim et al. 2020). In south-eastern Norway, this pattern is combined with a continuous
86 regression of the shoreline, following from isostatic rebound (e.g. Romundset et al. 2018; Sørensen 1979).
87 The fairly rapid shoreline displacement means that the sites tend not to have retained their strategic or
88 ecologically beneficial shore-bound location for long periods of time (cf. Perreault 2019:47). Consequently,
89 the shore-bound settlement, combined with the rapid shoreline displacement has resulted in a relatively high
90 degree of spatial separation of cumulative palimpsests, to follow the terminology of Bailey (2007), while the
91 reconstruction of the trajectory of relative sea-level change allows for a relatively good control of when these

B

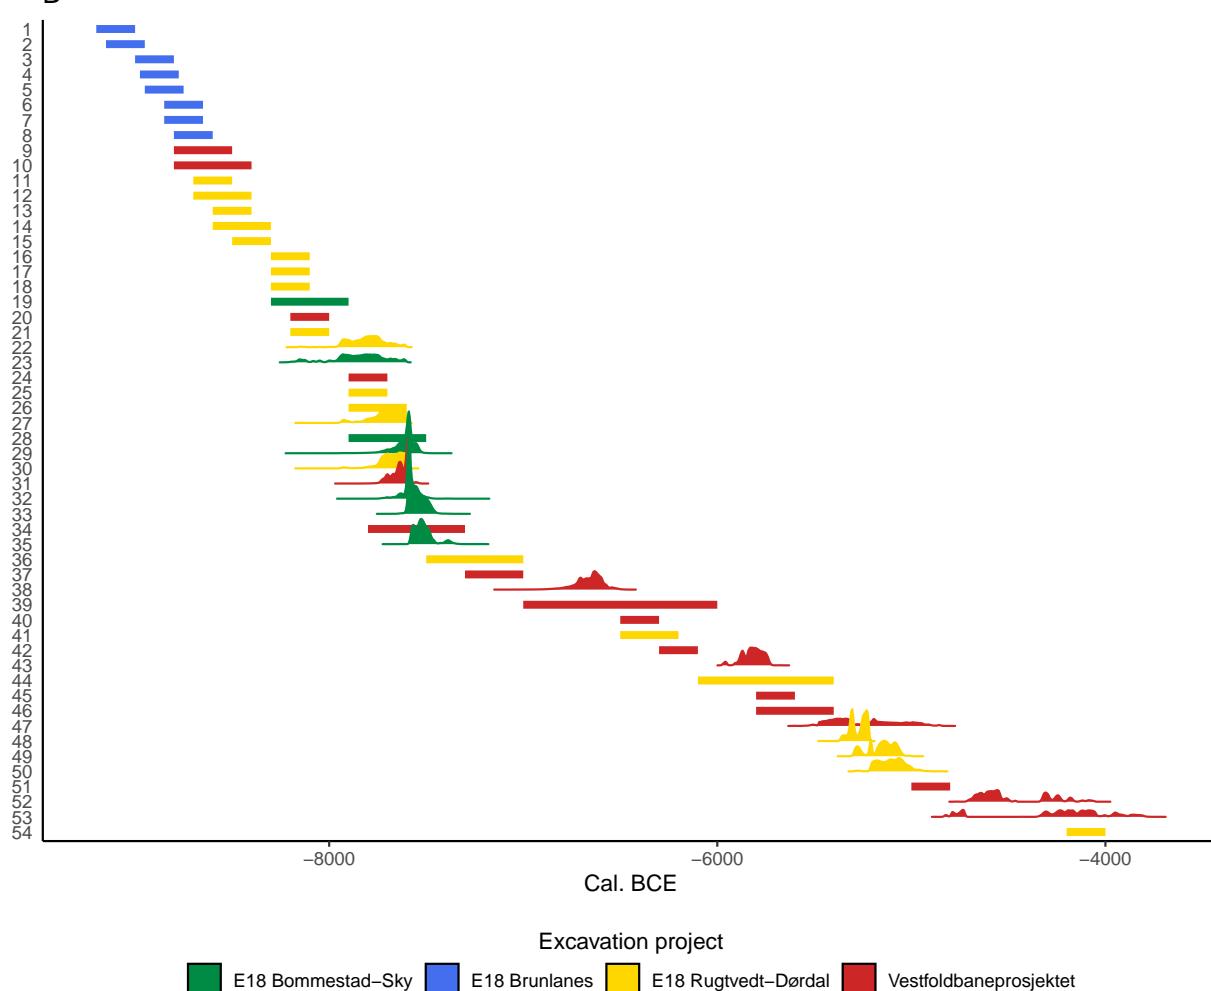

Figure 1: A) Spatial and B) temporal distribution of the sites chosen for analysis. Radiocarbon age determinations are given as the sum of the posterior density estimates. Solid lines indicate that the site has been dated with reference to relative sea-level change and typological indicators. These follow the original reports.

Table 1: Chronological framework. Glørstad's (2010) division of phases reflects the more traditional framework, to which Reitan (2016) has recently suggested considerable changes.

Glørstad (2010)	
Early Mesolithic, Fosna Phase	9500–8200 BCE
Middle Mesolithic, Tørkop Phase	8200–6300 BCE
Late Mesolithic, Nøstvet Phase	6300–4600 BCE
Late Mesolithic, Kjeøy Phase	4600–3800 BCE
Reitan (2016)	
Flake Axe Phase	9300–8200 BCE
Microlith Phase	8200–7000 BCE
Pecked Adze Phase	7000–5600 BCE
Nøstvet Adze Phase	5600–4500 BCE
Transverse Arrowhead Phase	4500–3900 BCE

92 accumulation events occurred. In other parts of the world, a higher degree of spatial distribution means that
 93 while the physical separation of material can help delineate discrete events, this typically comes at the cost of
 94 losing temporal resolution as any stratigraphic relationship between the events is lost (Bailey 2007).

95 The 54 coastal sites chosen for analysis here have a relatively limited geographical distribution (Figure 1A).
 96 The sites were excavated as part of four larger excavation projects that all took place within the last 15 years
 97 (Jaksland and Persson 2014; Melvold and Persson 2014; Reitan and Persson 2014; Solheim 2017a; Solheim
 98 and Damlien 2013). The sites included in the analysis consist of all Mesolithic sites excavated in conjunction
 99 with the projects that have assemblages holding more than 100 artefacts. The institution responsible for
 100 these excavations was the Museum of Cultural History in Oslo. This has led to a considerable overlap in the
 101 archaeological personnel involved, and comparable excavation practices across the excavations. Furthermore,
 102 with these projects, major efforts were made to standardise how lithic artefacts were to be classified at the
 103 museum (Koxvold and Fossum 2017; Melvold et al. 2014). As a result, this should reduce the amount of
 104 artificial patterning in the data incurred by discrepancies in the employed systems for categorisation (cf.
 105 Clark and Riel-Salvatore 2006; Dibble et al. 2017).

106 The lithic data analysed are based on the classification of the site assemblages done for the original excavation
 107 reports, and consists of 48 variables representing differentdebitage and tool types. The artefact data have
 108 been divided into flint and non-flint materials. Flint does not outcrop naturally in southern Norway, and is
 109 only available locally as nodules that have been transported and deposited by retreating and drifting ice (e.g.
 110 Berg-Hansen 1999). This means that the distribution and quality of flint has been impacted by a diverse set
 111 of climatic and geographical factors (Eigeland 2015:46). Thus, while flint is treated as a unified category here,
 112 the variability in quality could have been substantial. Furthermore, the various non-flint raw materials that
 113 have been lumped together have quite disparate properties, where fine-grained cryptocrystalline materials are
 114 often used as a substitute or supplement to flint, while other, coarser materials are usually associated with
 115 the production of axes and other macro tools. Given this differentiated use, these raw-material properties are
 116 expected to be reflected in the retaineddebitage and tool categories. An important benefit of combining all
 117 of the non-flint materials is that this reduces the dependency on whether or not these have been correctly
 118 and consistently categorised for the reports (cf. Frivoll 2017). Finally, while factors such as landscape
 119 changes through shoreline displacement can have led to variable raw-material availability at the analysed sites,
 120 their relatively constrained geographical distribution hopefully counteracts some non-behavioural sources of
 121 variation.

122 3 The analysis of lithic assemblages

123 Studies concerned with chronological changes in the composition of lithic assemblages in southern Norway have
124 typically had a focus on morphological variation among artefacts (e.g. Ballin 1999; Bjerck 1986; Reitan 2016)
125 or been concerned with technological processes associated with certain sub-categories of the site inventories,
126 such as the production of blades or axes (e.g. Berg-Hansen 2017; Damlien 2016; Eymundsson et al. 2018;
127 Solheim et al. 2020). Studies that have involved entire assemblages have either been concerned with general
128 compositional traits such as relative frequency of various tool types and raw-materials (Breivik 2020; e.g.
129 Breivik and Callanan 2016; Reitan 2016; Viken 2018), or involved extremely in-depth studies of technological
130 organisation associated with a handful of assemblages (Eigeland 2015; e.g. Fuglestvedt 2007; Mansrud and
131 Eymundsson 2016). These studies are, however, based on narratively driven methods, leaving the weighting
132 of the different variables for the final interpretations unclear. To my knowledge, only a single study dealing
133 with the composition of Mesolithic assemblages in southern Norway has involved the use of a multivariate
134 quantitative framework, which was employed to structure the analysis of eight Middle Mesolithic assemblages
135 (Solheim 2013; see Glørstad 2010:145–146 for a spatial application). In sum then, previous studies have
136 typically either been limited to a small number of sites, to a subset of the inventories, to morphological
137 characteristics, or to subjectively and narratively driven methods that are difficult to scale and consistently
138 balance in the comparison of a larger number of artefact categories and assemblages.

139 The aim of the first of part of the analysis conducted here is to evaluate the degree to which the composition
140 of the assemblages align with earlier studies that have employed more informal methods. This therefore
141 assumes that the artefact categories employed in Norwegian Stone Age archaeology are, at least to a certain
142 extent, behaviourally meaningful. However, the approach taken is also partially informed by the so-called
143 Frison effect (Jelinek 1976), which pertains to the fact that lithics studied by archaeologists can have had
144 long and complex use-lives in which they took on a multitude of different shapes before they were ultimately
145 discarded. Several scholars have built on this to argue that morphological variation in retouched lithics from
146 the Palaeolithic cannot be assumed to predominantly be the result of the intention of the original knapper to
147 reach some desired end-product, but rather that what is commonly categorised as discrete types of artefacts
148 by archaeologists can instead in large part be related to variable degrees of modification through use and
149 rejuvenation (e.g. Barton 1991; Barton and Clark 2021; Dibble 1995). Artefact categories believed not to
150 be internally consistent and categorically exclusive have therefore been collapsed for the analysis, as their
151 contribution as discrete analytical units could potentially be misleading.

152 However, for the most part we lack even a most basic understanding of what any individual lithic object in
153 an assemblage has been used for (Dibble et al. 2017). For example, a vast amount of artefacts defined as
154 debitage are likely to have fulfilled the function of tools, and both debitage and formal tool types could have
155 had various different purposes and had a multitude of shapes throughout their use-life. As a consequence, the
156 second part of the analysis employs a suite of measures developed for the classification of lithic assemblages
157 with these inferential limitations in mind (Barton et al. 2011; Clark and Barton 2017, and below). The logic
158 behind these measures are founded on an understanding of technology as being organised along a continuum
159 ranging between curated and expedient (Binford 1973, 1977, 1979). An expedient technological organisation
160 pertains to the situational production of tools to meet immediate needs, with little investment of time and
161 resources in modification and rejuvenation, resulting in high rates of tool replacement. Curated technological
162 organisation, on the other hand, has been related to manufacture and maintenance of tools in anticipation of
163 future use, the transport of these artefacts between places of use, and the modification and rejuvenation of
164 artefacts for different and changing situations.

165 However, following not least from the ambiguous definition first put forward by Binford (1973), the theoretical
166 definition of curation, its archaeological correlates, and behavioural implications have been widely discussed
167 and disputed (e.g. Bamforth 1986; Nash 1996; Shott 1996; Surovell 2009:9–13). Still, that the distinction can
168 offer a useful analytical point of departure if clearly and explicitly operationalised seems more or less agreed
169 upon, and some dimensions of the concept are generally accepted. For example, although precisely how it is
170 measured may vary, the empirical correspondent to a curated technological organisation is typically defined
171 by high degrees of retouch, as this is commonly seen as a means of realising the potential utility of a tool—or
172 extending its use-life—by the repeated rejuvenation and modification of edges (e.g. Bamforth 1986; Dibble

173 1995; Shott and Sillitoe 2005).

174 One concrete operationalisation of the terms has been forwarded by Barton (1998) and colleagues (e.g. Barton
175 et al. 1999, 2011, 2013; Barton and Riel-Salvatore 2014; Clark and Barton 2017; Riel-Salvatore and Barton
176 2004, 2007; Villaverde et al. 1998), who through a series of studies have shown that the relationship between
177 volumetric density of lithics and relative frequency of retouched artefacts in lithic assemblages have a consistent
178 negative relationship across a wide range of chronological and cultural context, ranging from Pleistocene and
179 Holocene assemblages in Europe and Asia, to assemblages associated with both Neanderthals and modern
180 humans (Barton et al. 2011; Riel-Salvatore et al. 2008). This relationship is taken to reflect degree of
181 curation, and is in turn mainly to follow from the accumulated nature of land-use and mobility patterns
182 associated with the assemblages (Barton and Riel-Salvatore 2014). Furthermore, the relationship between
183 curated and expedient technological organisation has been related to the continuum defined by Binford (1980)
184 between residentially mobile foragers and logically mobile collectors (Clark and Barton 2017; Riel-Salvatore
185 and Barton 2004; see also Bamforth 1986; Binford 1977). Residential mobility involves the relatively frequent
186 movement of entire groups between resource patches throughout the year, while logistic mobility entails the
187 use of central base-camps that are moved less often and from where smaller task-groups venture on targeted
188 forays to retrieve specific resources. A higher degree of logistic as opposed to residential mobility thus also
189 involves a wider range of site types and associated mobility patterns (Binford 1980).

190 Furthermore, in this model, higher degree of mobility would mean a higher dependency on the artefacts and
191 the material people could bring with them, and dimensions such as weight, reliability, repairability, and the
192 degree to which artefacts could be manipulated to fulfil a wide range of tasks are therefore assumed to have
193 been factors of concern. From this it follows that the empirical expectation for short-term camps is a curated
194 technological organisation with higher relative frequency of retouched artefacts, and a lower overall density of
195 lithics (Clark and Barton 2017). More time spent in a single location, on the other hand, is assumed to lead
196 to better control of raw-material availability and to allow for its accumulation. This should in turn lead to a
197 more expedient technological organisation with reduced necessity for the conservation of lithics and extensive
198 use of retouch. The empirical expectation for lower degree of mobility is therefore relatively high density of
199 lithics, a low relative frequency of retouched artefacts, as well as a higher number of unexhausted cores and
200 unretouched flakes and blades. These variables and underlying logic constitute what has been termed Whole
201 Assemblage Behavioural Indicators (WABI, Clark and Barton 2017), and is the main framework adopted
202 here.

203 As these measures are argued to predominantly be determined by land-use and mobility patterns, relative
204 frequency of chips and relative frequency of non-flint material are also included in the analysis, as these
205 measures have also been linked to mobility patterns and is of central importance in Norwegian Stone Age
206 archaeology (e.g. Bicho and Cascalheira 2020; Breivik et al. 2016; Kitchel et al. 2021; Reitan 2016)—the use
207 of local non-flint material has been taken to indicate reduced mobility and increased familiarity with local
208 surroundings (Glørstad 2010:181; Jakslund 2001:112).

209 4 Methodology

210 The exploratory approach taken here means that a wide range of combinations and transformations of
211 variables has been explored to identify patterning in the data. While only parts of this process can sensibly
212 be reported upon, the data and employed R programming script (R Core Team 2020) is freely available as a
213 research compendium at <https://osf.io/ehjfc/>, following Marwick et al. (2018), allowing readers to explore
214 and scrutinise the data and the final analytical choices made (Marwick 2017).

215 The 54 analysed sites have been dated by reference to relative sea-level change, typology and/or radiocarbon
216 dates (Table 2). Date ranges for sites based on shoreline displacement and typology are taken from the original
217 reports and follow the evaluation done by the original excavators. Where radiocarbon age determinations
218 believed to be associated with the lithic material are available, these have been calibrated using the IntCal20
219 calibration curve (Reimer et al. 2020) and subjected to Bayesian modelling using OxCal v4.4.4 (Bronk
220 Ramsey 2009) through the oxcAAR package (Hinz et al. 2021) for R. The only constraint imposed for the

modelling of the dates was that the dates from each site are assumed to represent a related group of events through the application of the Boundary function (Bronk Ramsey 2021). The resulting posterior density estimates were then summed for each site. Radiocarbon data are provided in the supplementary data (see also Solheim 2020).

The first part of the analysis involves employing the method of correspondence analysis (CA), using the lithic count data as classified for the original excavation reports. As this part of the analysis partially draws on the above-mentioned Frison effect, several artefact categories have been collapsed for the CA. This for example pertains to flint tool types such as scrapers, burins, drills, knives and otherwise indeterminate artefacts with retouch. These have all been combined into the single category “small flint tools.” (A full overview of the aggregated variables and their constituent parts is provided in the supplementary material). While aggregating artefact categories in this manner could potentially subsume important variation, it does also reduce the possibility that any conclusions are not simply the result of employing erroneous units of analysis.

Following the WABI and other factors associated with mobility patterns, as presented above, the variables employed in the second part of the analysis are relative frequency of secondarily worked lithics (RFSL), defined as the proportion of the assemblages constituted by retouched or ground lithics; volumetric density of lithics (VDL), defined as number of artefacts per excavated m³; relative frequency of chips, defined as the proportion of artefacts with size < 1 mm; relative frequency of cores, the proportion of all artefacts classified as cores in the original reports; relative frequency of blanks, here defined as the proportion of all artefacts classified as flakes, blades, micro-blades or fragments; and finally relative frequency of non-flint material. Following Bicho and Cascalheira (2020), the analysis is done using principal components analysis (PCA), leading to a shift in focus from the relative composition emphasised by the CA, to having more weight placed on patterning in the most abundant occurrences (Baxter 1994:71–77).

A note should also be made on the fact that a few variables that are sometimes invoked for the classification of sites in terms of associated mobility patterns are omitted here (e.g. Bicho and Cascalheira 2020; Breivik et al. 2016). For the assemblage data itself this especially pertains to diversity in tool-types (Canessa 2021), which has been omitted in light of the above-mentioned Frison effect. Number of features on the sites has also been disregarded as taphonomic loss is likely to have led to a chronological bias in their preservation. Similarly, the number of activity areas, effectively number of artefact clusters, however defined, has also been disregarded. This follows most notably from the fact that the impact of post-depositional processes at Stone Age sites in Norway is arguably understudied (Jørgensen 2017). This pertains for example to bio-turbation in the form of three-throws, which can have a detrimental effect on the original distribution of artefacts, and which can be expected to have impacted several of the sites treated here (Darmark 2018; Jørgensen 2017).

5 Results

The general impression from the CA is that a chronological dimension accounts for a substantial amount of patterning in the data (Figure 2). This is indicated by the general transition across the colour scale in the row plot (Figure 2A), the fact that the two first dimensions of the CA accounts for as much as 80.53 % of the inertia or variance in the data, as well as the horseshoe curve or Guttman effect evident in the column plot (Figure 2B, Baxter 1994:119–120).

The column plot reveals that the earliest sites are characterised by the flint artefact categories microburins, projectiles, as well as flint macro tools and associateddebitage. These assemblages are also to a larger extent characterised by core fragments, both in flint and non-flint materials, rather than cores. The non-flint material on the earliest, or among the earliest sites, appears to be centred around the production of projectiles, as both projectiles and non-flint blades are important constituents of the assemblages at these sites. The first dimension, which is pulling some of the later sites towards the right of the plot, is mainly defined by macro tools and associateddebitage in non-flint materials that are negatively correlated with more flint dominated assemblages. Site number 9, Nedre Hobekk 2, located in the upper right quadrant of the row plot represents a somewhat curious case in that it is an early assemblage characterised by axe production in metarhyolite (Eigeland 2014). However, the site had been quite heavily impacted by modern disturbances that could have

269 impacted the lithic material and which could explain its position as an outlier in the plot (Eigeland 2014).
270 Finally, although the sample size is quite strained and the discussion of finer chronological points might not
271 be warranted, the first dimension does appear to be of less importance for the absolute latest sites, as
272 indicated by their location to the left of the plot.

273 As most of the variation in the data is accounted for by the dominating non-flint material in later assemblages,
274 this suppresses and makes it difficult to discern patterns in the flint data. A second CA was therefore run
275 excluding the non-flint material (Figure 3). While not as substantial, there is clear temporal patterning in
276 the flint data as well. This is most marked for the earliest sites which are pulled away from the main cluster,
277 as projectiles, microburins, macro tools anddebitage from their production characterises these sites. Slightly
278 younger sites appear more impacted by core fragments and blades. The temporal transition in the main
279 cluster is not as marked, but clearly present, and is driven by a larger proportion of blades, flakes and small
280 tools in the earliest assemblages of the cluster, which is opposed to chips, fragments and partly micro-blades.

281 Moving on to the PCA of measures that have been linked to mobility, some of the variables with severely
282 skewed distributions were initially transformed (Figure 4). Figure 5 displays the resulting PCA. There is
283 a general temporal transition from the upper left to the bottom right of the plot. The second dimension
284 is mainly defined by a negative correlation between the VDL and RFSL (Figure 6). Almost orthogonal
285 to this is the strong negative correlation between relative frequency of chips and blanks. While there is
286 a slight tendency for blanks to be more associated with younger sites, frequency of chips appears to be
287 largely independent of time. However, this almost suspiciously strong negative correlation can perhaps have
288 a practical explanation. Seeing as the frequency of non-flint material is positively correlated with blanks and
289 negatively correlated with chips (Figure 4), one explanation to this pattern could be that smaller non-flint
290 pieces are simply more difficult to identify and separate from naturally fragmented stone during excavation
291 and classification. This could conceivably have led to an over-representation of blanks as compared to chips in
292 assemblages with a high proportion of non-flint material. While this is not necessarily the entire explanation,
293 this does make it difficult to place much analytical weight on this pattern. Relative frequency of cores is not
294 especially impactful in the PCA, and appears to be independent of the temporal dimension as well. That is
295 not to say that cores may not be indicative of or related to mobility patterns, but to get at this may require
296 further analysis beyond their simple classification as cores (Kitchel et al. 2021).

297 Thus, while some secondary expectations of the WABI do not seem to apply to the present material, it is
298 difficult to say to what degree this is caused by idiosyncrasies in the Norwegian system for classification of
299 lithics and properties of the lithic material itself. The relationship between VDL and RFSL does correspond
300 to the model and follows a clear temporal trend that is also correlated with the increased use of local raw
301 material. Thus, if the relationship between VDL and RFSL is accepted as a proxy for curation, and is related
302 to land-use and mobility patterns, these findings would be in line with previous research into the Mesolithic
303 of Norway, indicating that earlier sites are associated with higher degree of mobility than sites from later
304 phases (e.g. Bergsvik 2001; Bjerck 2008; Glørstad 2010; Jakslund 2001). To explore this proposition further,
305 these two variables are subjected to more detailed scrutiny below.

306 There is a strong negative correlation between the two variables ($r = -0.5$) and a general tendency for younger
307 sites to be associated with a higher VDL and a lower RFSL than older sites (Figure 7A). The linear correlation
308 is stronger between the mean site age and RFSL ($r = -0.51$), than between mean site age and VDL ($r = 0.22$).
309 Variable non-flint availability and workability has also been suggested to potentially impact these dimensions
310 (cf. Manninen and Knutsson 2014), but while the negative correlation is slightly less marked when only the
311 flint data is considered ($r = -0.4$), the general pattern is the same (Figure 7B). The relationship between mean
312 site age and relative frequency of secondarily worked flint is even stronger ($r = -0.57$), but as indicated by
313 the more spread out distribution along the x-axis, the volumetric density of flint is not temporally contingent
314 ($r = 0.1$). As was also indicated by the CA, this follows from the fact that non-flint materials make up a
315 higher share of the assemblages for some of the later Mesolithic sites, and is a point returned to below where
316 the temporal dimension of the relationship between VDL and RFSL is explored further.

317 To get more directly at this temporal trend, a curation index based on VDL and RFSL was devised by first
318 performing a min-max normalisation of the two variables, scaling them to take on values between 0 and 1.
319 The value for artefact density was then made negative to reflect its relationship with degree of curation. The

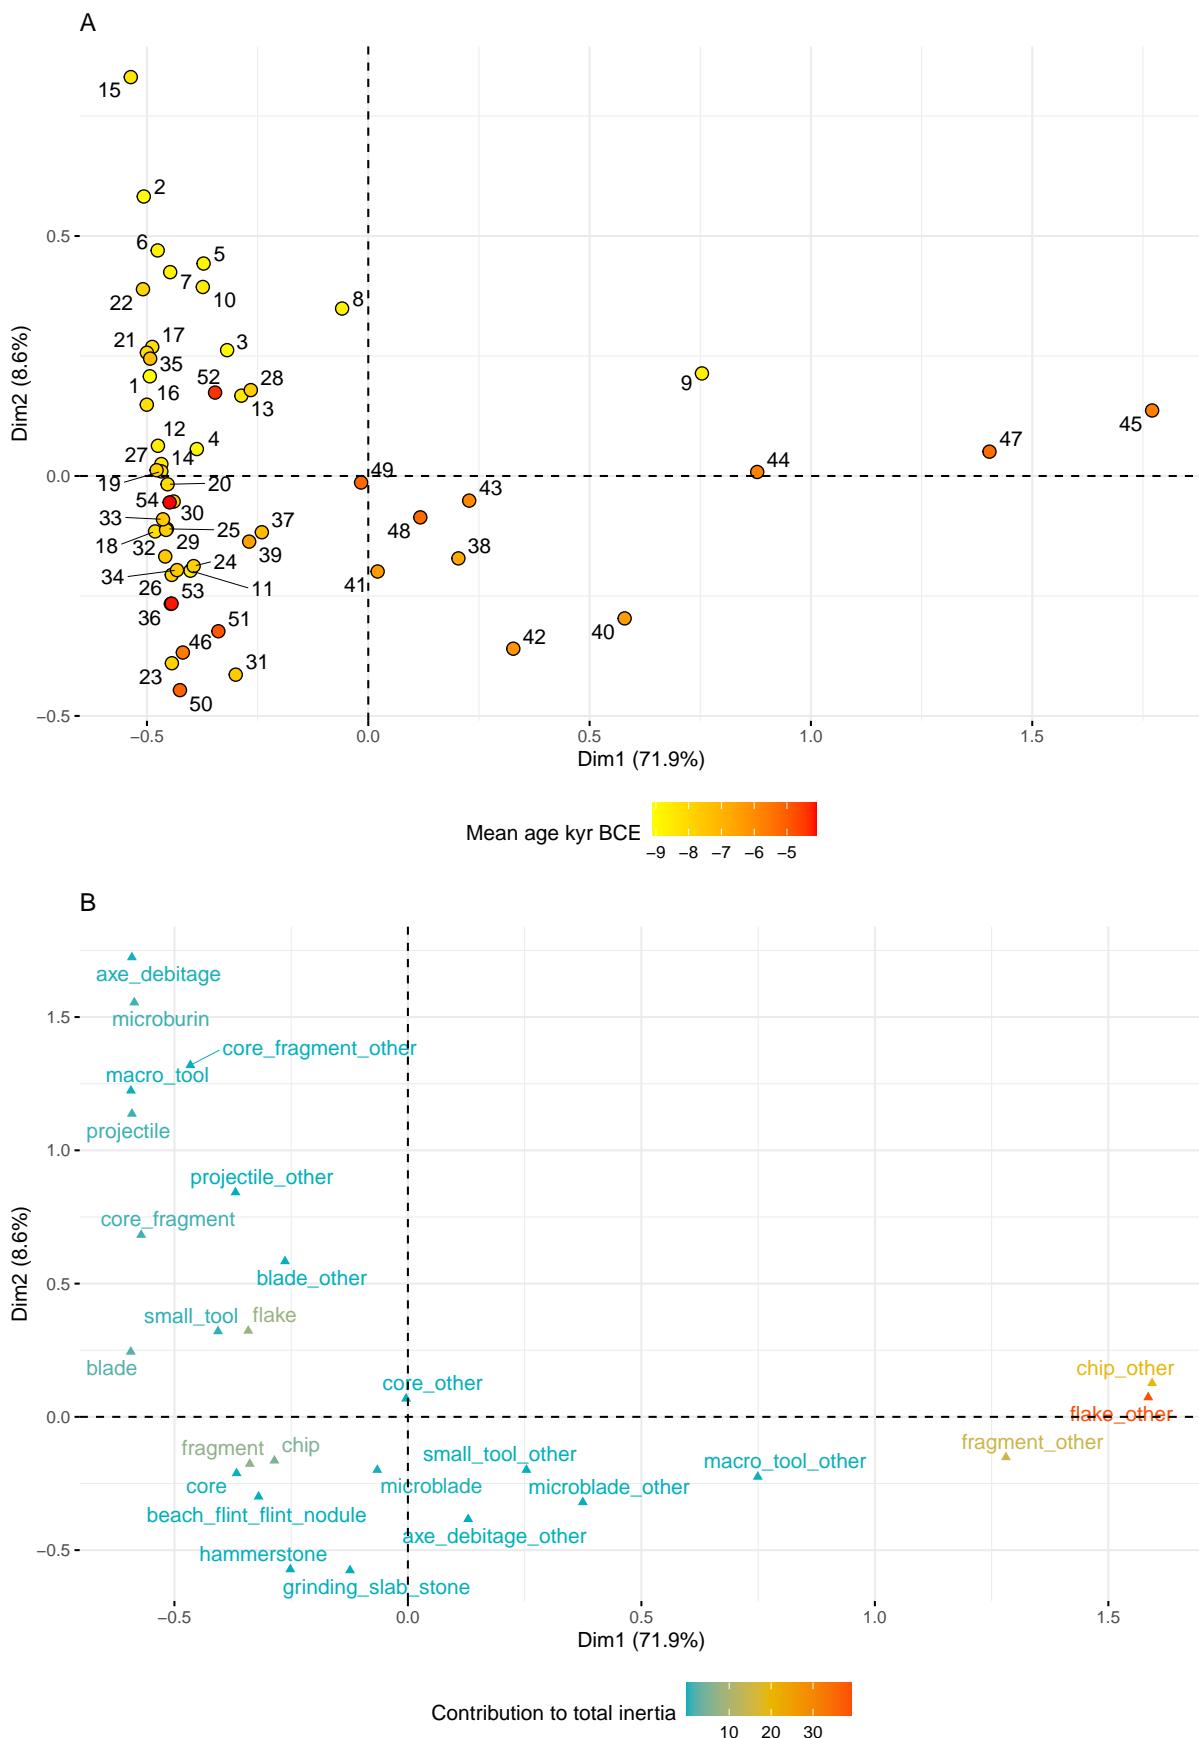

Figure 2: Correspondence analysis using the artefact count data. A) Row plot, B) Column plot.

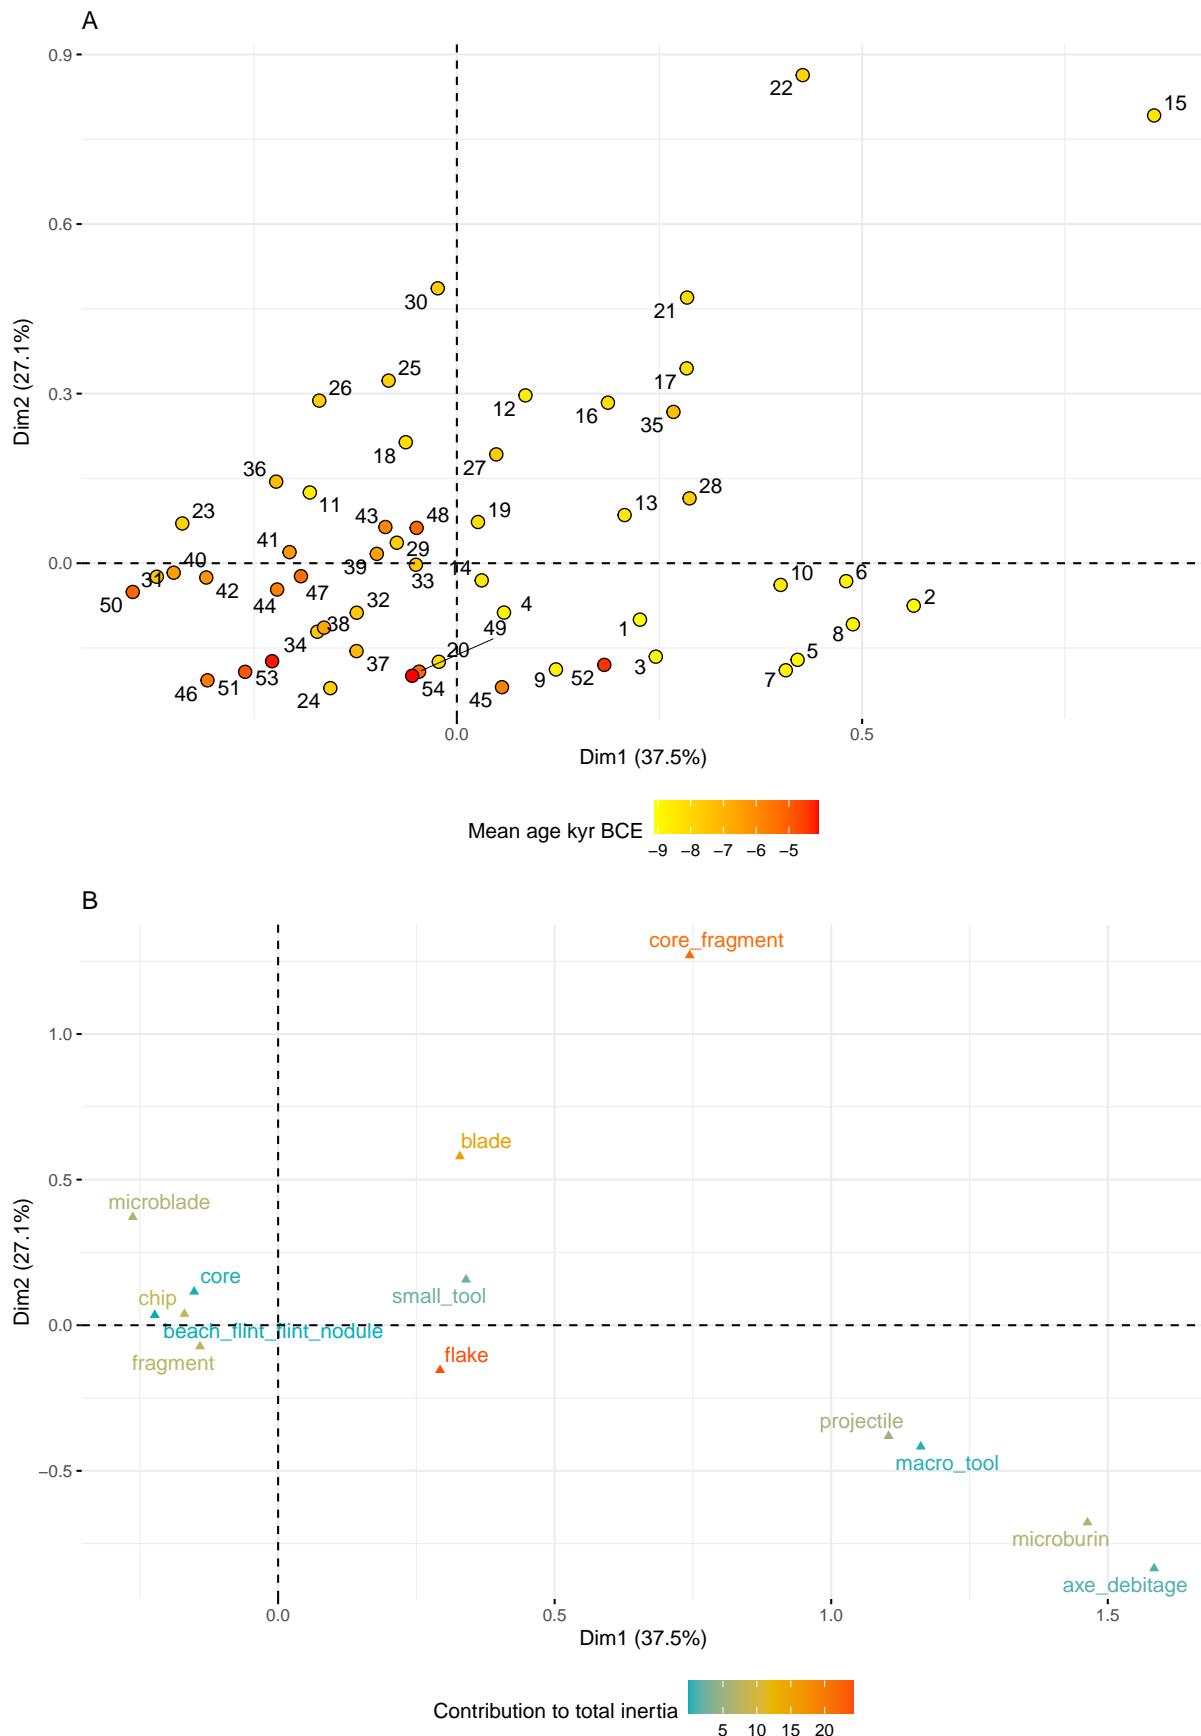

Figure 3: Correspondence analysis using the flint data. A) Row plot, B) Column plot.

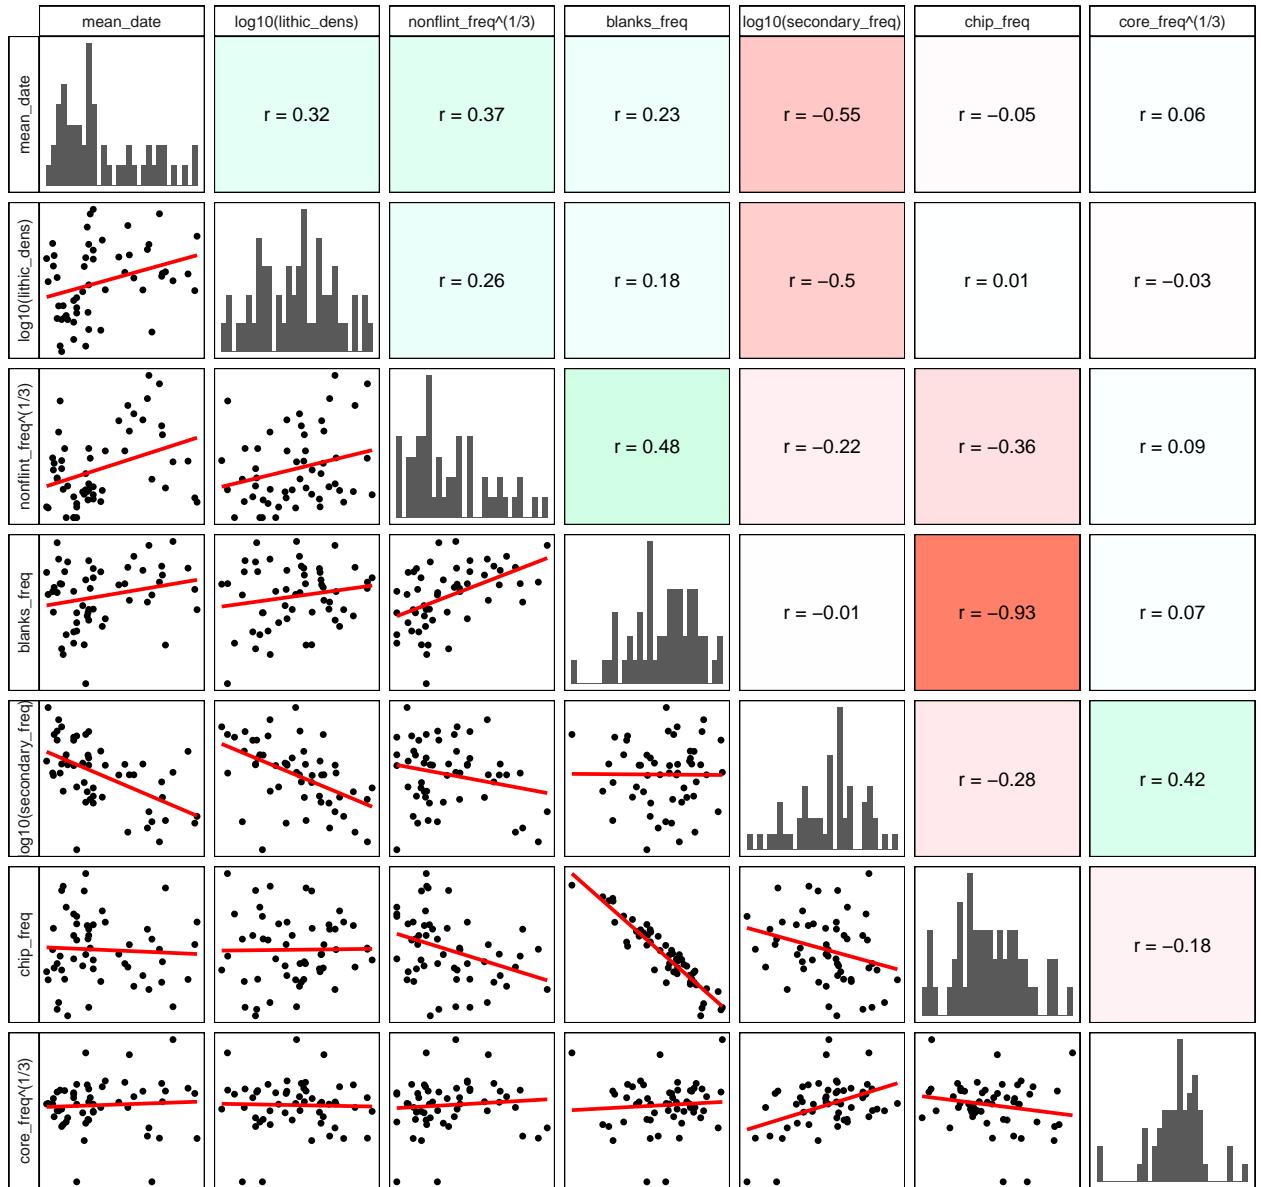

Figure 4: Correlation matrix showing transformation of skewed variables for the PCA. The mean age of the sites has also been included to visualise overall temporal trends. Cells below the diagonal display the bivariate distributions with a fitted OLS-regression. The cells above the diagonal display and are coloured by the corresponding Pearson's correlation coefficient.

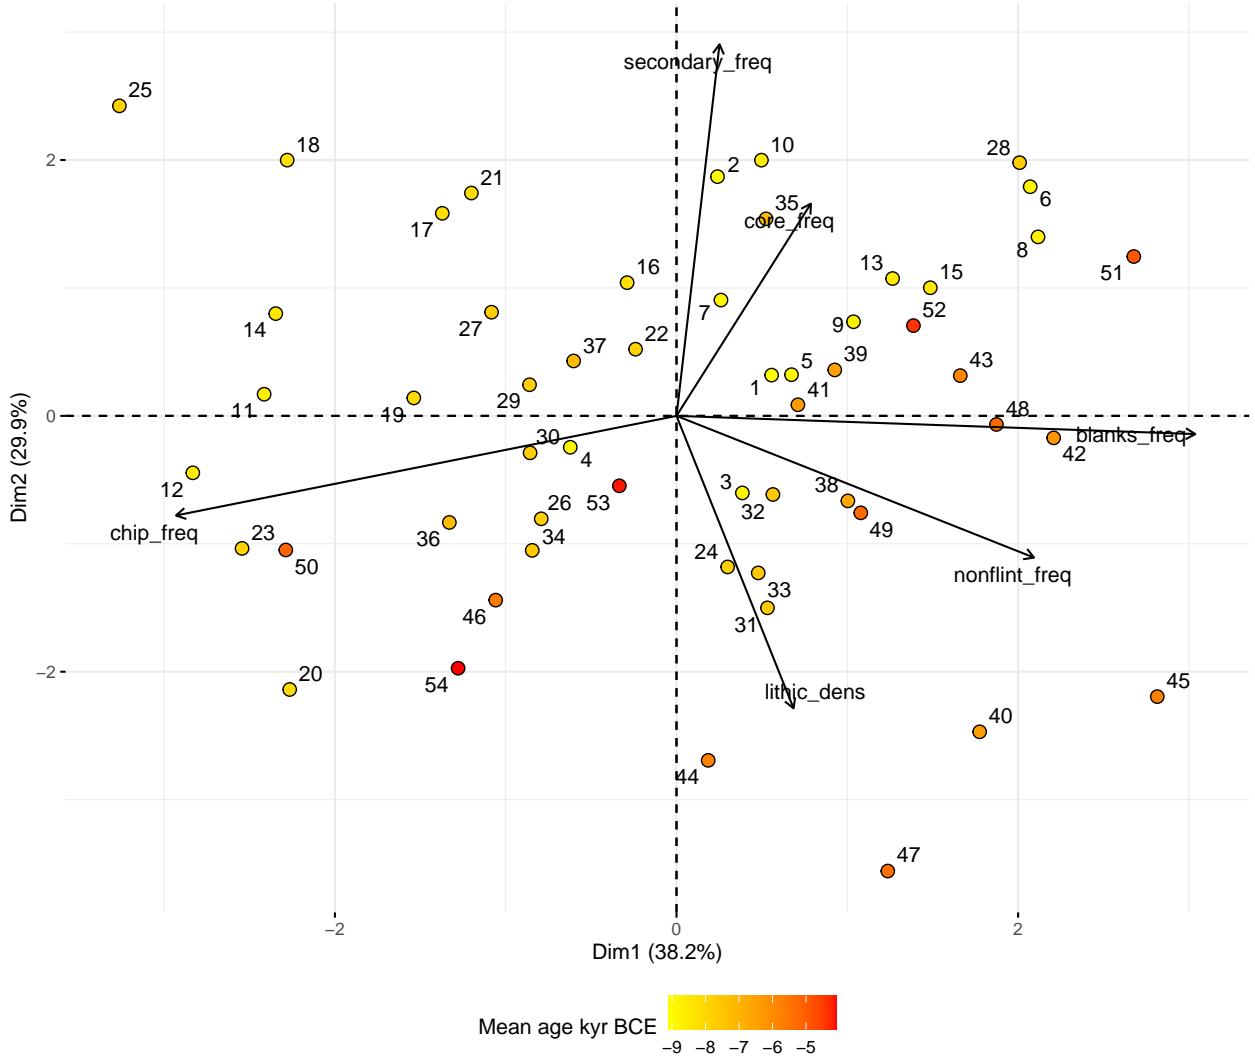

Figure 5: PCA using variables that have been related to mobility patterns. Note that details on the transformation of the variables has been left out of the plot for clarity, but follow those given in Figure 4.

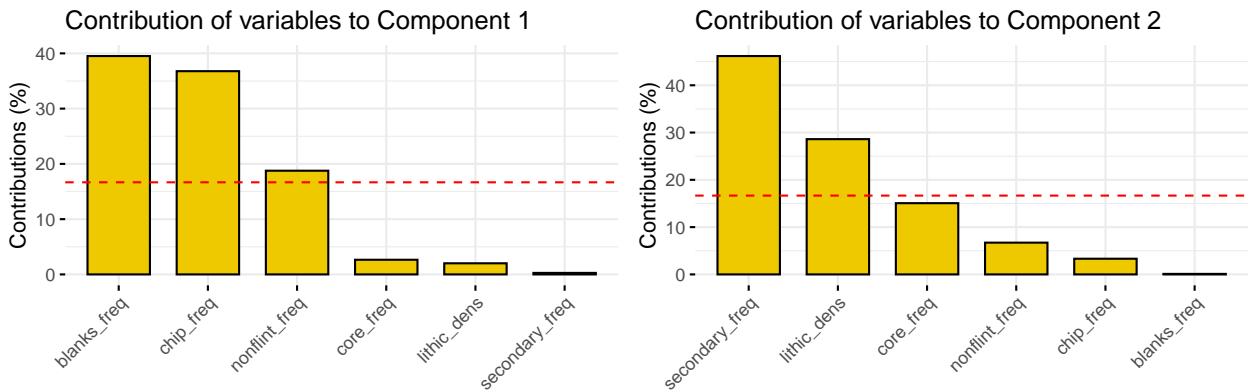

Figure 6: Contribution of variables to the first two components of the PCA. The dotted red line indicates the expected contribution from each variable given a uniform distribution of impact.

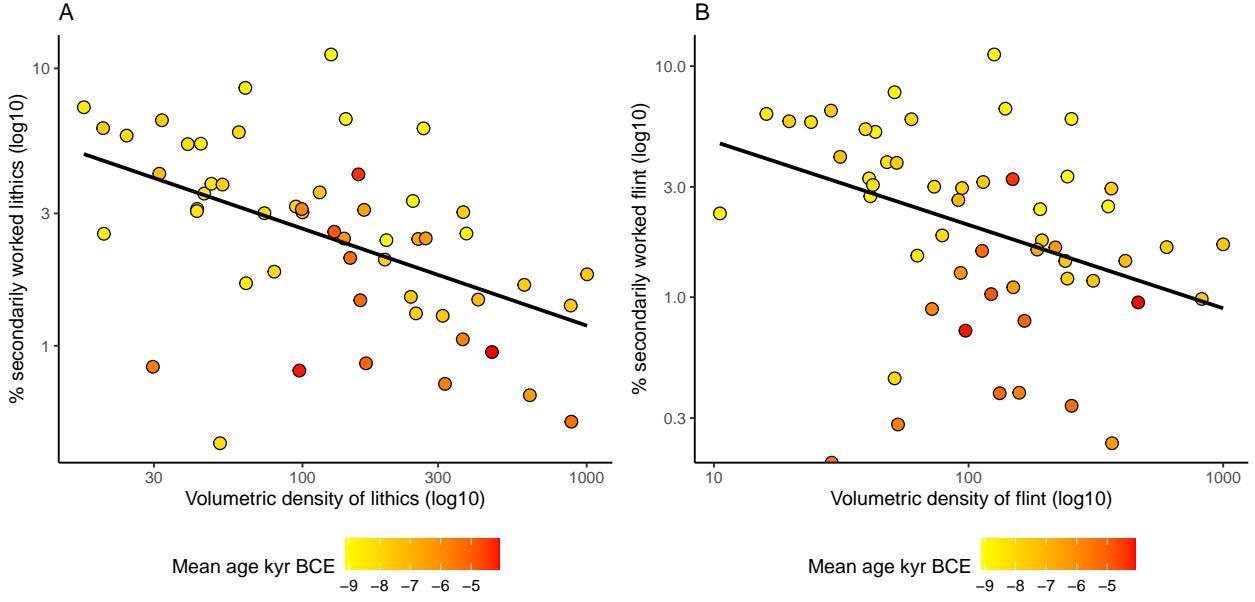

Figure 7: Relative frequency of secondarily worked lithics plotted against the volumetric density of artefacts for A) All lithics, B) Flint. The logarithm is taken to base 10 on all axes.

mean was then found for each site on these two normalised values. To account for the temporal uncertainty associated with the dating of the sites, a simulation-based approach was also adopted (e.g. Crema 2012; Orton et al. 2017). A LOESS curve was fit to the curation index and site age for each simulation run, where the age of each site was drawn as a single year from their respective date ranges as provided in Figure 1. For sites with radiocarbon age determinations the dates were drawn from the summed posterior density estimates, while ages for sites dated with reference to relative sea-level change and typology were drawn uniformly from the associated date range (Figure 8). This simulation was repeated 1000 times. Disregarding the edge-effects at either end of the plot, the general tendency is a relatively high degree of curation among the earlier sites, followed by a marked drop around 8000 BCE. This has stabilised by around 7000 BCE and remains stable for the rest of the Mesolithic. The variation in degree of curation is also markedly higher after 8000 BCE. Figure 8B displays the result of running the same procedure on the flint data. The general pattern follows the same trajectory, but the result for some individual sites is noticeably different.

6 Discussion

The results of the CA appear to align well with previous research (e.g. Solheim 2017b, with references). In the flint material the earliest sites are separated from the rest primarily based on the presence of macro tools, microburins, projectiles, and, for slightly younger sites, core fragments and blades (cf. Bjerck 2017; Breivik et al. 2018; Damlien and Solheim 2018; Fuglestvedt 2009; Jakslund and Fossum 2014). The importance of the latter two can be associated with the blade technology that is introduced with the Middle Mesolithic, characterised by blade production from conical and sub-conical cores with faceted platforms that involves the removal of core tablets and rejuvenation flakes (Damlien 2016). When it comes to the non-flint material, projectiles are to a larger extent a property of the earlier sites than later ones. The use of metarhyolite for the production of axes is present at some earlier sites in addition to the previously mentioned Nedre Hobekk 2, and the production of non-flint hatches and core axes is introduced in the Microlith Phase (Eymundsson et al. 2018; Jakslund and Fossum 2014; Reitan 2016). However, in agreement with the literature, this is evidently not as prominent a part of these assemblages.

The flint material of the later sites are to larger extent characterised by micro-blades, which corresponds to

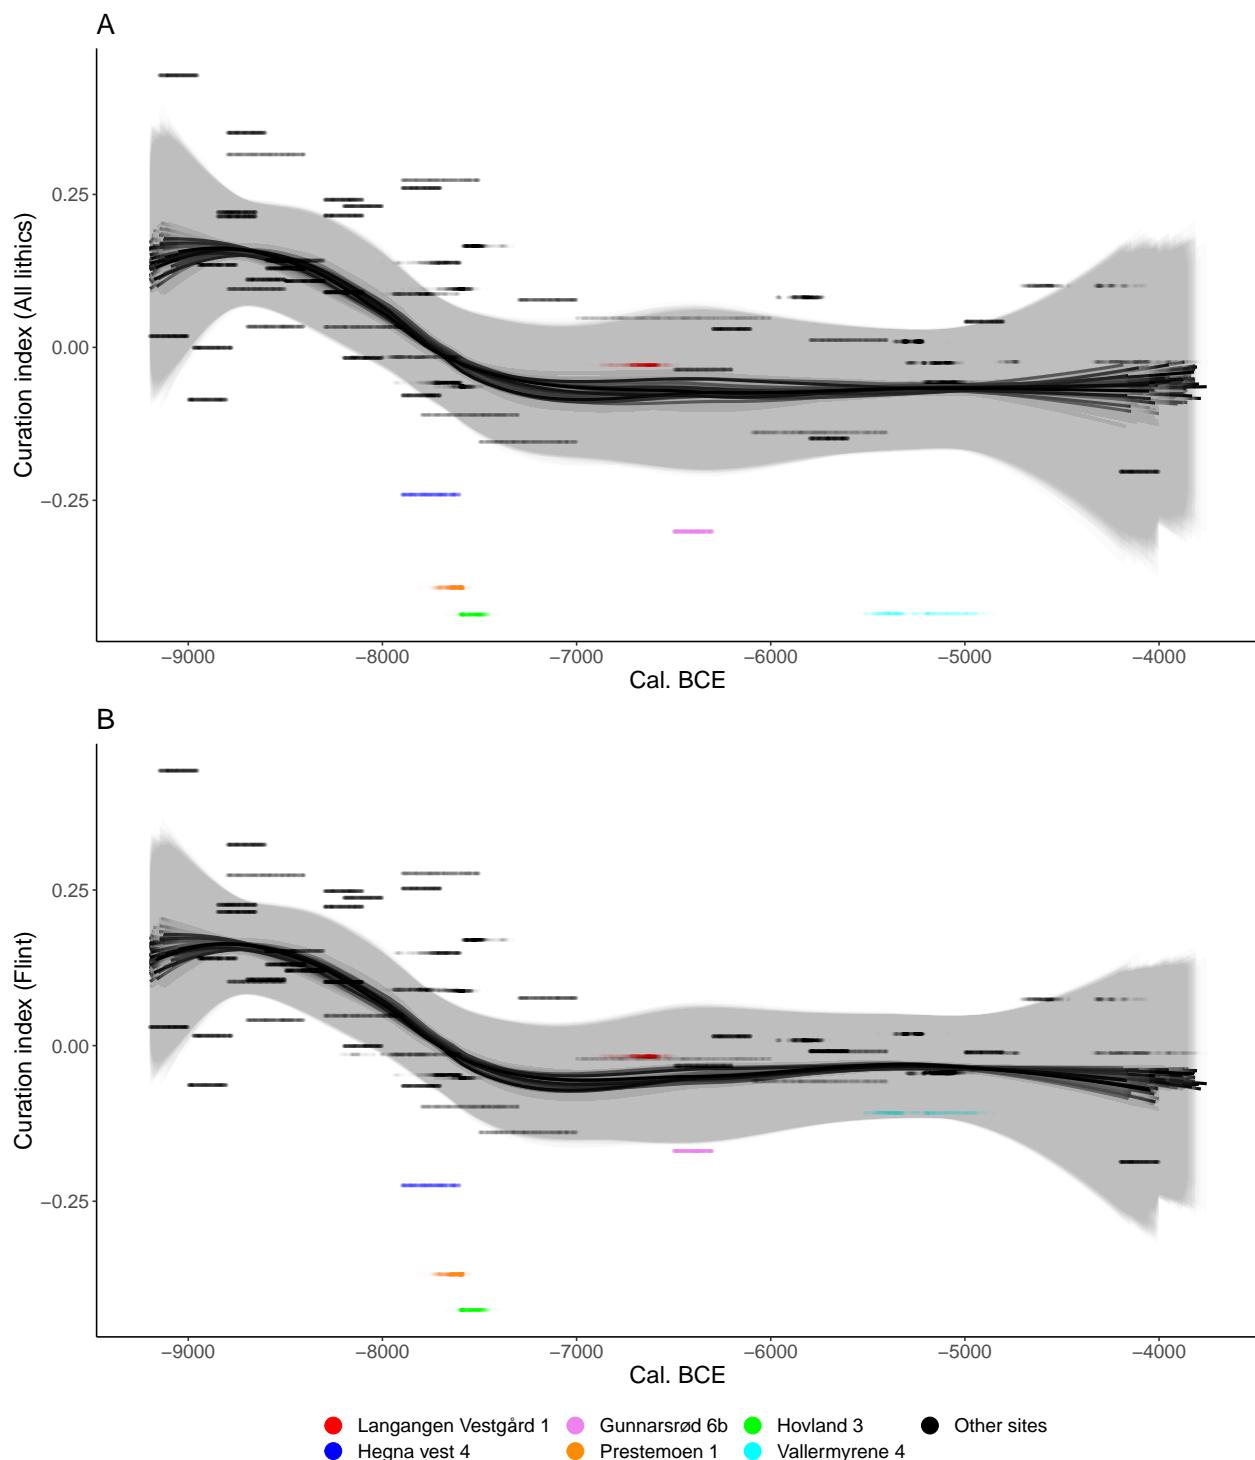

Figure 8: Temporal variation in the curation index for A) All lithics, and B) Flint. The temporal uncertainty is handled by means of a simulation approach where the site ages are drawn from their respective age determination probability density functions given in Figure 1B. A LOESS curve has been fit to the distribution for each of the 1000 simulation runs. Each simulation run is plotted with some transparency. Sites mentioned in the text are given colour.

346 the transition to micro-blade production from handle cores (e.g. Solheim et al. 2020). A more fragmented
347 flint material, as indicated by the relative importance of flint chips and fragments, is also a previously noted
348 property of some later Mesolithic, as well as early Neolithic sites (e.g. Fossum 2017; Stokke and Reitan 2018).
349 The most defining material for the later sites, however, is non-flint macro tools and associated debitage, which
350 is dominating some of these assemblages. It was noted above that this material does not seem to impact
351 the latest sites, which would indicate that specialised axe production sites disappear towards the end of the
352 Mesolithic, a notion that would be in line with previous suggestions (e.g. Glørstad 2011; Reitan 2016).

353 One implication of the fact that the employed artefact categories are so clearly capturing a temporal component
354 could be that the aggregation of artefact categories might have been overly conservative. However, it is also
355 evidently clear, in the words of Kruskal (1971:22), that ‘time is not the only dimension.’ The results of the CA
356 do most certainly correspond to more pervasive cultural change than a purely typo-chronological development
357 of artefact morphology, which is also made evident by some significant deviances from the overall pattern.
358 Unpicking and aligning these patterns with any specific behavioural and technological dimensions using the
359 coarse CA results is, however, another task entirely. This follows most clearly from the fact that for the
360 most part we do not know what individual lithic objects in the assemblages have been used for, leaving the
361 behavioural and social significance of the employed units of analysis unclear. The results of the CA can,
362 however, be used in conjunction with the part of the analysis that has attempted to get at more specific
363 behavioural dimensions to nuance or explain discrepancies in this data.

364 The curation index has relatively high values until some time before 8000 BCE, before it drops and stabilises
365 around 7000 BCE. This pattern is evident in both the flint data and when all lithics are treated in aggregate.
366 Furthermore, the increased variation in degree of curation after around 8000 BCE could indicate that these
367 sites were associated with a more varied mobility pattern. The five sites that have values on the curation
368 index below c. -0.25 could in this perspective have predominantly functioned as base-camps within a logistic
369 settlement pattern. That these assemblages reflect stays of a longer duration was suggested for all five sites
370 in the original reports (Carrasco et al. 2014; Eigeland and Fossum 2017; Persson 2014; Solheim and Olsen
371 2013), with the exception of for Vallermyrene 4, which was argued to be a specialised axe production site, not
372 necessarily associated with lower degrees of mobility (Eigeland and Fossum 2014). This highlights a possible
373 issue pertaining to raw-material variability, as the coarse non-flint material used for the production of axes
374 generally results in a relatively large amount of waste per produced tool, possibly skewing the curation index
375 when compared to assemblages dominated by flint. Referring back to the CA, the difference is most marked
376 for the sites in the later part of the Mesolithic where non-flint material become more dominating parts of the
377 assemblages. As can be seen in Figure 8B, the degree of curation is markedly higher for both Gunnarsrød
378 6b and Vallermyrene 4 when the non-flint material is excluded, although they remain more expedient than
379 that of contemporary assemblages. Thus, the degree of expediency for assemblages dominated by non-flint
380 might be somewhat exaggerated when the non-flint material is included, while its exclusion would likely lead
381 to its underestimation. One possible approach could be to weigh the curation index by the proportion of
382 non-flint material in the assemblages. This is not explored further here, however, as the overall tendencies
383 are relatively robust to this effect.

384 Another case also worth commenting on is Langangen Vestgård 1, which, on the grounds of an overall large
385 number of artefacts and the possible presence of a dwelling structure was argued to reflect a more permanent
386 site location in the original report (Molvold and Eigeland 2014). However, the relatively high value on the
387 curation index could mean that the site reflects the aggregation of stays which predominantly have been of a
388 comparable duration to those on contemporary sites, while the possible dwelling structure, if taken as an
389 indication of longer stays, could in this perspective represent a remnant from one or a few visits of longer
390 duration that constitute a smaller fraction of the use-life of the site as a whole (cf. Barton and Riel-Salvatore
391 2014).

392 While there are certainly nuances in the material that might lead one to question the applicability of the VDL
393 and RFSL measures for any individual site, the overall pattern for curation does appear relatively robust. The
394 curation index is relatively high and uniform until some time before 8000 BCE. This corresponds well with
395 the view that the Early Mesolithic is characterised by a high and uniform degree of mobility. This is followed
396 by a marked increase in expediency, which has stabilised by around 7000 BCE. Again, this corresponds well
397 with the employed chronological framework. Referring back to the demographic changes that are to take

398 place around this transition, the Microlith phase could thus represent a period where migrating people and
399 new living practices were propagating through societies in south-eastern Norway—a process that in light of
400 the curation data would have concluded around 7000 BCE.

401 The curation index then remains stable for the rest of the Mesolithic. This suggests that the transition to
402 mobility patterns traditionally ascribed to the Nøstvet Phase can indeed be traced back to the Microlith
403 Phase (cf. Solheim and Persson 2016). The continued stability of the curation index could also indicate that
404 the demographic changes suggested to take place in the Transverse Arrowhead Phase are not related to major
405 shifts in land-use and mobility patterns. However, it is worth highlighting the strained sample size for the
406 later parts of the Mesolithic, which could mean that the effect is simply missed.

407 As it stands, the main hypotheses resulting from the present analysis would be that settlement patterns in
408 the earliest parts of the Mesolithic were characterised by relatively high and uniform degrees of mobility,
409 which then drop before levelling off at around 7000 BCE. These then remain relatively stable throughout the
410 rest of the period, despite variation pertaining to other aspects of the lithic inventories, as evidenced by the
411 CA. The fall in curation levels and parallel increase in variation would seem to correlate well with a transition
412 from a predominantly residential to logistical settlement system (Binford 1980). This indicates, in turn, that
413 the measures represent an empirical link between technological organisation and economic behaviour and
414 mobility patterns (Riel-Salvatore and Barton 2004).

415 7 Conclusion

416 The results of the CA align well with results of previous research in south-eastern Norway, indicating that
417 meaningful chronological patterning is associated with the employed artefact categories. These tendencies are
418 already well-established when it comes to the formal tool types and some debitage categories, but have been
419 given less focus in light of entire assemblages. Precisely what behavioural implication the development in the
420 occurrences of the tool and debitage categories have are less clear, but appears to follow a different and more
421 complex development over time than that of curation, as operationalised here.

422 The temporal trends associated with the curation index corresponds surprisingly well with trajectories of
423 cultural development previously suggested in the literature, and does therefore, in my view, suggest that
424 shifts in land-use and mobility patterns are the main drivers behind this empirical pattern—in line with the
425 framework of Barton et al. (2011). Another perspective would be that this is not surprising at all (cf. Kuhn
426 and Clark 2015:14), and that the previously demonstrated relevance of these measures across a wide range
427 of contexts points to their pervasive relevance for the organisation of lithic technology, and, therefore, that
428 there should be little reason to think Mesolithic south-eastern Norway should be any different. However,
429 the conclusion that these these measures apply to and appear to capture the dimensions of interest in a
430 relatively controlled empirical setting, reached by means of an exploratory analysis can only constitute a first
431 analytical step. As Elster (2015:12) has pointed out, the human mind seems to have a propensity to settle
432 for an explanation that *can* be true, as soon as this has been reached. This, however, can only constitute
433 the absolute minimum of what is required of a proposed explanation. Subsequent steps should be to probe
434 and challenge this explanatory framework, also in light of alternative hypotheses. The empirical relationship
435 does nonetheless hold great potential for large scale comparative studies in Mesolithic Scandinavia and
436 beyond. Furthermore, the curation index was here simply narratively associated with the most immediate
437 chronological trends emphasised in the literature concerned with the Mesolithic of south-eastern Norway.
438 The explicit quantification does, however, offer the possibility to conduct formal comparisons with a wide
439 range of environmental, demographic and cultural dimensions across multiple scales of analysis.
